ABSTRACT

We present an approach and architecture for implementing scalable and maintainable clinical decision support at the Partners HealthCare System. The architecture integrates a business rules engine that executes declarative if-then rules stored in a rule-base referencing objects and methods in a business object model. The rules engine executes object methods by invoking services implemented on the clinical data repository. Specialized inferences that support classification of data and instances into classes are identified and an approach to implement these inferences using an OWL based ontology engine is presented. Alternative representations of these specialized inferences as if-then rules or OWL axioms are explored and their impact on the scalability and maintenance of the system is presented. Architectural alternatives for integration of clinical decision support functionality with the invoking application and the underlying clinical data repository; and their associated trade-offs are discussed and presented.

INTRODUCTION

Clinical care guidelines specify best practices in clinical care and are intended to improve safety, quality and cost effectiveness³ of patient care. As payers such as the Federal Government (Medicare, Medicaid) and insurance agencies (e.g., Blue Cross Blue Shield) move towards a pay for performance model, quality metrics, e.g., JCAHO¹ and HEDIS² measures have come into focus. We seek to incorporate these metrics into our clinical information systems.

Approaches for modeling and automation of clinical practice guidelines have been proposed over the years: the Arden Syntax⁴, EON⁵, PRODIGY-3⁶, PROforma⁷, Asbru⁸, GUIDE⁹, Prestige¹⁰ and GLIF3¹¹. From an architectural viewpoint, GLIF3 deserves special discussion. The various steps in the GLIF3 guideline model have been delineated as³: action and decision steps to represent clinical actions and decisions; patient state steps to serve as entry points into a guideline; and branch and synchronization steps for modeling concurrency. In

this paper, we present an approach for clinical decision support that subscribes to GLIF3 architectural principles by using an industrial strength Business Rules Engine - iLOG¹³, and an OWL¹⁶ ontology engine, Cerebra¹⁴.

We present an approach for architecting rule content that represents patient state encapsulated in classes and methods of a business object model. These classes and methods are referenced in a rule base containing a set of declarative if-then rules. The "if part" of a rule typically consists of boolean conditions on the patient state. The "then" part consists of actions such as updating the patient state, making clinical recommendations, and specifying medication orders, etc. We also propose further delineation of decision support logic into definitions and decisions, where definitions correspond to characterization of patient states and classes; and decisions correspond to clinical recommendations and orders. Definitions are used to classify a given patient to a particular state on the basis of her documented clinical profile. This leads to a modular architecture for decision support, and easier maintenance of rules in the face of changing definitions. Finally, architectural alternatives for integration of the clinical decision support component with the invoking application and the clinical data repository are discussed.

USE CASE

Consider the following guideline for lipid management suggested by the American Diabetes Association (ADA)¹²:

Lowering triglycerides and increasing HDL cholesterol with a fibrate are associated with a reduction in cardiovascular events in patients with clinical CVD, low HDL and near-normal levels of LDL (A). Lower triglycerides to <150 mg/dL (1.7 mmol/L) and raise HDL cholesterol to >40 mg/dL (1.15 mmol/L). In women, an HDL goal 10 mg/dL higher may be appropriate (C). Patient has CVD, triglycerides >150 and/or HDL<40 (for women HDL<50) and LDL levels are near normal.

The steps for implementing the above clinical guideline are: (1) Create the *Business Object Model* that defines patient related classes and methods; (2) Specify *Rules* to encode Decision Support logic; and (3) Delineate definitions characterizing patient states and classes and represent them in an *Ontology*.

BUSINESS OBJECT MODEL DESIGN

The business object model for the above guideline could be specified as follows:

```
Class Patient
method get_gender(): string;
method has_diabetes(): boolean;
method has_CVD(): boolean;
method get_last_triglycerides(): real;
method get_last_HDL(): real;
method get_last_LDL(): real;
```

The model defines a class and methods to characterize patient state information. These methods are executed by the rules engine leading to invoking of services on the clinical data repository to retrieve patient data. Additional conditioning of retrieved patient data may also be performed, leading to interesting design choices for business object model design and implementation.

Consider the methods has_diabetes() and has_CVD(), that determine whether a patient has diabetes or cardiovascular disease respectively. An alternative could a method get_diseases() that return a list of diseases which a patient suffers from. Whether the disease diabetes or CVD is on that list can be checked by the rule engine by executing a rule defined for that purpose. This simplifies the business object model, but introduces complexity in rule execution. The current design leverages optimized processing in the clinical data repository and reduces complexity of rule creation.

Consider the method <code>get_last_triglycerides()</code> that retrieves the last triglycerides reading for a patient from the clinical data repository. This approach assumes the existence of a service on the clinical data repository which would return the last triglycerides reading for a patient. In some cases, computations to determine the "last" triglycerides reading may be implemented as a method in the business object model or as a rule in the rule base.

RULE BASE DESIGN

The business object model presented in the earlier section provides the vocabulary to specify various rules for implementing the clinical guideline.

```
IF the_patient.get_gender() = "male"
AND the_patient.has_CVD() = "true"
AND the_patient.get_last_triglycerides()>=150
AND the_patient.get_last_HDL()<=40
AND the_patient.get_last_LDL()>=Value1
AND the_patient.get_last_LDL()<=Value2
THEN "order fibrate therapy"</pre>
```

The above rule represents the first part of the diabetes guideline. A special variable "the_patient" acts as a placeholder for the actual patient being evaluated.

The definition of "near normal LDL" is modeled by assuming that the LDL reading of the patient lies between <code>value1</code> and <code>value2</code>. The next rule is similar to the above but has a higher threshold for HDL values for women and can be specified as follows:

```
IF the patient.get_gender() = "female"
AND the patient.has_CVD() = "true"
AND the patient.get_last_triglycerides()>=150
AND the patient.get_last_HDL()<=50
AND the patient.get_last_LDL()>=Value1
AND the_patient.get_last_LDL()<=Value2
THEN "order fibrate therapy"
```

There are alternative ways of specifying these rules. For instance, the two rules above can be combined into one rule as follows:

This representation reduces the number of rules in the rule base which has a beneficial impact both on rule execution and maintenance. However, the rule specification has now become more complex for a knowledge author to understand and vet the rule for clinical validity effectively.

DEFINITIONS VS DECISIONS

Clinical decision support rules encode different types of inferences:

- Rule-based specifications of conditions that describe patient states and classes, for instance, "Diabetic Patient with Higher Risk for CVD" or characterize normal or near normal physiological patient states, for instance, "Patients with near normal values of LDL". These specifications are also called *definitions*.
- Rule-based specifications that propose therapies, medications and referrals, for instance, prescribing fibrate therapy for a diabetic patient with higher risk for CVD. These specifications are called decisions.

This provides us with an opportunity to further modularize our rule base by separation of the definition of a "Diabetic Patient with high risk of CVD", from decisions such as "Prescribe fibrate therapy". The definitions in the rule base can be represented as follows:

The simplified rule base can now be represented as:

Definitions of various patient states can be represented as axioms in an ontology that could be executed by an OWL ontology engine, Cerebra¹⁴. At execution time, the ILOG rule engine can invoke a service that interacts with the Cerebra OWL engine to infer whether a particular patient belongs to a given class of patients, in this case, a diabetic patient with high risk of cardiovascular disease. The ontology of patient states and classes can be represented as follows:

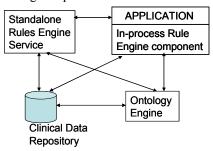

```
Class Patient
ObjectProperty gender
ObjectProperty hasDisease
ObjectProperty lastTriglycerides
ObjectProperty lastLDL ObjectProperty lastHDL
Class DiabeticPatient
≡ Patient ∩ ∃hasDisease.Diabetes
Class CVD
Class Diabetes
Class Disease
CVD \subseteq Disease
Diabetes ⊆ Disease
Class LDLNearNormal
Class HDLLessThan50
Class HDLLessThan40
Class TriglyceridesMoreThan150
Class DiabeticPatientWithHigherRiskofCVD
■ DiabeticPatient ∩ ∃hasDisease.CVD ∩
∀lastTriglycerides.TriglyceridesMoreThan150
[[∀gender.{"male"}∩∀lastHDL.HDLLessThan40]∪
[∀gender.{"female"}∩∀lastHDL.HDLLessThan50]]
```

The specification of various definitions in the ontology is illustrated above. For simplicity, we have adopted a non-XML based notation although they will be implemented following the OWL specification¹⁶. The class *Patient* and properties gender, hasDisease, lastTriglycerides, lastLDL and lastHDL provide a framework for describing the patient. The class *DiabeticPatient* is a subclass of all patients that are known to suffer from diabetes. This is expressed using an axiom following the Patient class definition. The class *Disease* represents various diseases and subclasses of interest, CVD and Diabetes. The classes LDLNearNormal,

HDLLessThan40 HDLLessThan50, and TriglyceridedMoreThan150 represent ranges of values of normal LDL, HDL and Triglycerides respectively. Cerebra has implemented custom datatypes based on the OWL specifications¹⁶, providing the ability to map XML Schema17 datatypes to OWL Classes and supports range checking inferences on them. Finally, DiabeticPatientWithHigherRiskofCVD is defined using an axiom to characterize diabetic patients with higher risk of CVD. The representation of this axiom enables the rule author to simplify the rule base significantly (as only the rule in bold needs to be specified). The classification of a patient as being diabetic and with high risk of CVD is now performed by the Cerebra Ontology Engine.

CLINICAL DECISION SUPPORT ARCHITECTURE

An architecture for implementing clinical decision support systems is illustrated below and consists of the following components:

Clinical Data Repository: The clinical data repository stores patient-related clinical data. External applications, the rule engine and the ontology engine retrieve patient data by invoking services implemented by the clinical data repository. Standalone Rules Engine Service: A standalone rules engine service is implemented using the ILOG business rules engine. On receiving a request, the service initializes a rule engine instance, loads the rule base and business object model. The rule engine service then executes methods in the business object model and performs rule based inferences. The results obtained will then be returned to the invoking application.

In-process Rule Engine Component: This provides similar functionality to the rules engine service, except that the rule engine component is loaded in the same process space in which the application is executing.

Ontology Engine: This will be implemented using the Cerebra Server. On receiving a request, the ontology engine performs classification inferences on patient data to determine if a patient belongs to a particular category, e.g., high risk patient. We now revisit the design patterns discussed earlier and evaluate the trade-offs associated with them. In cases, where there is a lot of interaction between the invoking application and the decision support component, including it as an in-process component may reduce the time taken for execution as network latency between rule engine invocations will be minimized. Caching of the patient state is likely to play a significant role in execution efficiency. For instance, in the case where specialized services check whether a patient has diabetes, is not available on the clinical data repository, the complete patient object will need to be populated so that the rule engine can check for existence of diabetes in the list of patient diseases. Efficient mechanisms to check, refresh and dispose cached patient state information will be required.

For large rule bases, the ability of the rule engine to leverage Rete Rule Matching computation¹⁴ to rapidly identify rules that are likely to fire will be crucial. Designing rule bases with a minimal set of rules will also be useful in speeding up rule engine execution. As illustrated earlier, combining two rules into one may be helpful as it would result in one rule (as opposed to two) being loaded on the agenda. Identification of a set of classification inferences that can be implemented by an ontology engine and invoked as a service from the rules engine offers significant potential for speeding up execution performance of the rules engine. A significant proportion of clinical decision support involves classification and this could result in reducing overhead on the rules engine and speeding up execution performance.

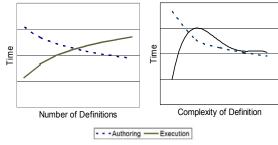

RULE AUTHORING AND MAINTENANCE CONSIDERATIONS

Some of the design patterns discussed earlier will have an impact when it comes to rules authoring and maintenance. The compactness of the business object model makes the job of maintenance easier. For instance, it's better to have a method for retrieving patient diseases rather than a large number of methods for checking the existence of a potentially large number of diseases a patient could have. On the other hand, this could increase the complexity of the rule base, should this checking be done via a specialized rule. The ability to create a compact rule base by combining two or more rules into a single rule (as illustrated earlier) also makes the maintenance of the rule base easier. However, this could make the individual rules more complex and difficult to understand, impacting the ease of rule reuse and editing.

The separation of definitions from decisions and their implementation in an ontology engine reduces the complexity of the rule base maintenance significantly. It may be noted that the conditions that comprise a definition may appear multiple times in multiple rules in a rule base. Our approach enables the encapsulation of these conditions in a definition. for e.g., DiabeticPatientWithHighRiskofCVD. Thus can now reference rules the class DiabeticPatientWithHighRiskofCVD which defined and maintained as a part of an ontology in the ontology engine. Whenever the definition of DiabeticPatientWithHighRiskofCVD changes, they can be isolated within the ontology engine and the rules that reference this definition can be easily identified.

EVALUATION AND LESSONS LEARNED

We present initial experiences in applying an ontology-based approach for clinical decision support. The key parameters that were monitored are as follows: (a) The complexity and number of OWL definitions used in the clinical decision support knowledge base; (b) The effort required for rule authoring and quality assurance (Q/A); and (c) The time taken for execution of clinical decision support inferences. Some trends are summarized below. These trends are not conclusive but do represent do suggest the viability of our approach.

We now present some interesting lessons learned.

- As more OWL definitions are introduced, the same knowledge can now be expressed in a more concise manner by referencing these definitions. This reduces the time for rule authoring. However, the use of OWL definitions has a negative impact on rules execution performance in comparison to a vanilla rules engine architecture, primarily due to round trip communication costs between the ontology and rules engines.
- As we increase the complexity of definitions by encapsulating in them earlier, more granular definitions, the total number of definitions decreases. This mitigates the negative impact on execution observed by the introduction of definitions, above. At the same time rule authoring efficiencies are introduced as the same set of rules with multiple conditions on the "if" part of the

rules are now represented in a concise manner. This is due to the encapsulation of these conditions in an OWL definition, enabling the rule author to specify a reference to the definition as opposed to specifying multiple conditions.

There is a tradeoff between efficiencies gained in rule authoring and the negative impact on rule execution performance (as compared to a vanilla rules engine architecture). An optimal configuration needs to be identified to achieve the improvements in total cost of ownership. This cost savings due to rule authoring efficiencies can be used to invest in load balancing infrastructure to achieve the required level of business performance. Crucial to achieving the efficiencies discussed above is the effective modularization of a rule base such that the inferences performed by a rule engine and an ontology do not overlap. We were able to achieve this in specific cases, but it requires more investigation.

CONCLUSIONS AND FUTURE WORK

We have presented an approach and architecture for implementing clinical decision support in a healthcare delivery system. An example clinical guideline was represented by designing a business object model that describes patient information and a rule base that makes inferences and suggests actions based on patient state. Furthermore, we propose delineation between definitions and decisions and the use of an ontology engine for performing classification inferences. This motivated an architecture for invocation of an ontology engine from a rules engine. A service oriented approach for retrieving information from the clinical data presented. repository was Alternative implementations of a rule engine component as an inprocess component and as a stand alone service were also proposed. Different design decisions and tradeoffs were discussed in the context of this architecture along with their impact on rule authoring and maintenance. Practical Usefulness considerations were discussed and lessons learned were also presented.

The work described in this paper is part of an ongoing project at Partners HealthCare to use an industrial strength business rules engine, ILOG and an ontology engine, Cerebra for implementing clinical decision support. Creation of a robust rules authoring and maintenance environment for rapid and consistent update of decision support knowledge is also being architected. We will investigate the following issues going forward: (a) To what extent is it possible to isolate changes in definitions and the business object model from rules? (b) What will be the impact of genomic and personalized medicine on clinical guidelines? Will our architecture be able to

manage knowledge related to personalized medicine? (c) Can semantic web technologies and reasoners based on OWL enable design of enhanced decision support and knowledge maintenance? Will this help support clinical decision support requirements for personalized medicine?
